Abstract

Algorithms from the book Nash (1979) are implemented in a variety of programming languages including Fortran, BASIC, Pascal, Python and R.

Overview of this document

A companion document **Overview of Nashlib and its Implementations** describes the process and computing environments for the implementation of Nashlib algorithms. This document gives comments and/or details relating to implementations of the algorithms themselves.

Note that some discussion of the reasoning behind certain choices in algorithms or implementations are given in the Overview document.

Algorithms 1 and 2 – one-sided SVD and least squares solution

These were two of the first algorithms to interest the first author in compact codes. At the time (1973-1978) he was working at Agriculture Canada in support of econometric modeling. More or less “regular” computers required accounts linked to official projects, but there was a time-shared Data General NOVA that offered 4K to 7K byte working spaces for data and programs in interpreted BASIC. BASIC of a very similar dialect was available also on an HP 9830 calculator. On these machines, availability of a terminal or the calculator was the only limitation to experimentation with recent innovations in algorithms. In particular, a lot of modeling was done with linear least squares regression, mostly using the traditional normal equations. The singular value decomposition and other methods such as the Householder, Givens or Gram-Schmidt approaches to the QR matrix decomposition were relatively recent innovations. However, the code for the Golub-Kahan SVD was rather long for both the hardware and the BASIC language. Instead, a one-sided Jacobi method was developed from ideas of Hestenes (1958) and Chartres (1962). Some work by Kaiser (1972) was also observed. Later workers have generally credited Hestenes with this approach, and he certainly wrote about it, but we (JN) suspect strongly that he never actually attempted an implementation. In a conversation at a conference, Chartres said that some experiments were tried, but that he believed no production usage occurred. We must remember that access to computers until the 1970s was quite difficult.

The method published in Nash (1975) and later revised in Nash and Shlien (1987) ignored some advice that Jacobi rotations should not use angles greater than $\pi/4$ (see Forsythe and Henrici (1960)). This allowed of a cyclic process that not only developed a form of the decomposition, but also sorted it to effectively present the singular values in descending order of size. This avoided extra program code of about half the length of the svd routine.

About 2 decades after Nash (1975), there was renewed interest in one-sided Jacobi methods, but rather little acknowledgment of the earlier development, and much more complicated codes. ?? How far to reference more recent developments??

Fortran

Note that these are single precision codes. Very few modern calculations are carried out at this precision. Moreover, the dialect of Fortran (Fortran 77) is now decidedly old-fashioned, though it compiles and executes just fine.

```

Special implementations

Most singular value decomposition codes are much, much more complicated than Algorithm 1 of the Nashlib collection. For some work on the magnetic field of Jupiter for NASA, Sidey Timmins has used an extended

(quad) precision version of the method. One of us (JN) has converted an updated algorithm (Nash and Shlien (1987)) to the Fortran 95 dialect so the multiple precision FM Fortran tools of David M. Smith (see <http://dmsmith.lmu.build/>).

?? include this code and example in the repo??

?? Could we f2c the Fortran and manually tweak to get a C code?

There is also a C version in

<https://github.com/LuaDist/gsl/blob/master/linalg/svd.c>

=====

Algorithm 3 – Givens' decomposition

The Givens and Householder decompositions of a rectangular m by n matrix A ($m \geq n$) both give an m by m orthogonal matrix Q and an upper-triangular n by n matrix R whose product QR is a close approximation of A . At the time Nash (1979) was being prepared, the Givens approach seemed to give a more compact program code, though neither approach is large.

In practice, if one is trying to solve linear equations

$$Ax = b$$

or linear least squares problems of the form

$$Ax = b$$

then the right hand side (RHS) b can be appended to the matrix A so that the resulting working matrix

$$W = [A|b]$$

is transformed during the formation of the Q matrix into

$$W_{trans} = [R|Q'b]$$

This saves us the effort of multiplying b by the transpose of Q before we back-solve for x .

In fact, m does not have to be greater than or equal to n . However, underdetermined systems of equations do raise some issues that we will not address here.

It is therefore unnecessary to store Q , which when Nash (1979) was being prepared was a potentially large matrix. There are alternative designs of the code which could save information on the plane rotations that make up Q . Such codes can then apply the rotations to a unit matrix of the right size to reconstruct Q as needed. However, these details have largely become irrelevant in an age of cheap memory chips.

Algorithm 9 – Bauer-Reinsch matrix inversion

Wilkinson, Reinsch, and Bauer (1971), pages 45-49, is a contribution entitled **Inversion of Positive Definite Matrices by the Gauss-Jordan Method**. It hardly mentions, but appears to assume, that the matrix to be inverted is symmetric. Two Algol procedures are provided, one for a matrix stored as a square array, the other for the a matrix where only the lower triangle is stored as a single vector in row-wise order. That is, if A is of order $n=3$ and has values

```
1  2  4
2  3  5
4  5  6
```

Then the corresponding vector of $6 = n*(n+1)/2$ values is

```
1  2  3  4  5  6
```

By some exceedingly clever coding and matrix manipulation, Bauer and Reinsch developed tiny codes that invert a positive-definite matrix *in situ* using only one extra vector of length n . Thus, besides the memory to store a very small code, we need only $n*(n+3)/2$ floating point numbers and a few integers to index arrays.

Truthfully, we rarely need an explicit matrix inverse, and the most common positive-definite symmetric matrix that arises in scientific computations is the sum of squares and cross-products (SSCP) in the normal equations used for linear (or also nonlinear) least squares problems. However, the formation of this SSCP matrix is rarely the best approach to solving least squares problems. The SVD introduced in Algorithm 1 and the least squares solution in Algorithm 2 lead to better methods. (??mention A4, Choleski in A7, A8 etc.)

Despite these caveats, the Bauer-Reinsch algorithm is interesting as a historical curiosity, showing what can be done when resources are very limited.

Others

Algorithm 10 – Inverse iteration via Gaussian elimination

The purpose of this algorithm is to find a single eigensolution of a matrix A via inverse iteration. That is, we want solutions (e, x) of

$$Ax = ex$$

The programs do not require a symmetric matrix, which leaves open the possibility that a solution may not exist in the unsymmetric case.

Fortran

The Algorithm 10 code:

Algorithms 11 and 12 – standardization and residuals for a complex eigensolution

These algorithms are probably among the least used of those included in Nashlib. Their intent was to allow proposed eigensolutions of complex matrices to be standardized and tested. This seemed a potentially important task in the 1970s. ?? include COMEIG (ref to Eberlein’s work, others??)

The purpose of standardization is to facilitate comparisons between eigenvectors that are supposedly equivalent. Any (preferably) unit-length multiple of an eigenvector is also an eigenvector, so it is difficult to compare two proposed solutions for the same eigenvalue. Therefore we choose a multiplier so that the largest magnitude component of the eigenvector is set to $1 + 0i$ where

$$i = \sqrt{-1}$$

Fortran

The Algorithm 11 code:

```

      SUBROUTINE A11VS(N,X,Y,VNORM)

Example output

We illustrate by finding a single eigensolution of the Hilbert segments of order 5 and 10. ?? Do we want to swap in the Frank matrix (the computations are generally easier)?

```
## #!/bin/bash
gfortran ../fortran/a1112.f
mv ./a.out ../fortran/a1112.run
../fortran/a1112.run <../fortran/a1112.in

```

Pascal

Currently we do not seem to have a separate example driver for these two codes. However, they are used in conjunction with the example(s) for Algorithm 26 (Complex matrix eigensolutions).

Listing – Algorithm 11

```

procedure stdceigv(n: integer;
                  var T, U: rmatrix);

var
  i, k, m : integer;
  b, e, g, s : real;

begin
  writeln('alg11.pas -- standardized eigensolutions');
  writeln(confile, 'alg11.pas -- standardized eigensolutions');
  for i := 1 to n do
  begin
    g := T[1,i]*T[1,i]+U[1,i]*U[1,i];

    k := 1;
    if n>1 then
    begin
      for m := 2 to n do
      begin
        b := T[m,i]*T[m,i]+U[m,i]*U[m,i];
        if b>g then
        begin
          k := m;

```

```

        g := b;
    end;
end;
end;
e := T[k,i]/g;
s := -U[k,i]/g;
for k := 1 to n do
begin
    g := T[k,i]*e-U[k,i]*s; U[k,i] := U[k,i]*e+T[k,i]*s; T[k,i] := g;
end;
end;
end;
end;

```

Listing – Algorithm 12

```

procedure comres( i, n: integer;
                  A, Z, T, U, Acopy, Zcopy : rmatrix);

var
    j, k: integer;
    g, s, ss : real;

begin
    writeln('alg12.pas -- complex eigensolution residuals');
    writeln(confile,'alg12.pas -- complex eigensolution residuals');
    ss := 0.0;
    for j := 1 to n do
    begin
        s := -A[i,i]*T[j,i]+Z[i,i]*U[j,i]; g := -Z[i,i]*T[j,i]-A[i,i]*U[j,i];

        for k := 1 to n do
        begin
            s := s+Acopy[j,k]*T[k,i]-Zcopy[j,k]*U[k,i];
            g := g+Acopy[j,k]*U[k,i]+Zcopy[j,k]*T[k,i];
        end;
        writeln('(' ,s ,',',g ,')'); writeln(confile,'(' ,s ,',',g ,')');
        ss := ss+s*s+g*g;
    end;
    writeln('Sum of squares = ',ss); writeln(confile,'Sum of squares = ',ss);
    writeln; writeln(confile);
end;

```

Algorithm 15 - Generalized symmetric eigenproblem

We aim to solve the generalized symmetric eigenproblem

$$Ax = eBx$$

for x and e , where symmetric matrices A and B and B is positive definite.

Fortran

Listing – Algorithm 15

```

```

Example output

This example uses the Frank matrix as B and a Unit matrix as matrix A . Essentially we get the eigensolutions of the inverse of the Frank matrix.

Algorithm 16 – Grid search

Grid search – establishing a regular pattern of parameter values for one or more arguments of a function and then evaluating that function on the “grid” – is a brute force approach to finding roots, minima, maxima and other features of a function surface. While it cannot be recommended as an efficient method for finding roots or minima, it offers a way to generate data for plotting the function surface and for localizing roots or minima when these are not unique. Furthermore, it is readily understood, and offers a useful starting point in presenting and understanding a problem.

Example output

The driver for presenting the example of the Pascal version of Algorithm 16 is combined with that of Algorithm 17 below.

Algorithm 17 – Minimize a function of one parameter

It is helpful to be able to visualize a one-parameter function before trying to find a minimum. R provides a nice way to do this, and also provides (via the **Brent** method of `optim()`) a way to seek a local minimum, though we need to provide lower and upper bounds. The original Algorithm 17 from Nashlib uses a starting guess and a starting stepsize, which leads to a different approach to finding a minimum. However, the upper and lower bound approach was used in the 1990 Second Edition and its Turbo Pascal variant of the code.

```

cubfn <- function(x) { x*(x*x-2)-5}
curve(cubfn, from=-2, to=2)

```

```

res <- optim(par=0.0, fn=cubfn, method="Brent", lower=c(0), upper=c(1))
cat("Minimum proposed is f(",res$par,")=",res$value,"\n")

```

```
## Minimum proposed is f( 0.8164966 )= -6.088662
```

Pascal

Example output

First we compile the codes.

```

fpc ../Pascal2021/dr1617.pas
# copy to run file
mv ../Pascal2021/dr1617 ../Pascal2021/dr1617p.run

```

```

## Free Pascal Compiler version 3.0.4+dfsg-23 [2019/11/25] for x86_64
## Copyright (c) 1993-2017 by Florian Klaempfl and others
## Target OS: Linux for x86-64
## Compiling ../Pascal2021/dr1617.pas

```

```
## Linking ../Pascal2021/dr1617
## /usr/bin/ld.bfd: warning: link.res contains output sections; did you forget -T?
## 282 lines compiled, 0.1 sec
```

Then we run the grid search (Algorithm 16) followed by the line search routine (Algorithm 18).

```
../Pascal2021/dr1617p.run <../Pascal2021/dr1617p.in >../Pascal2021/dr1617p.out
```

Algorithm 18 – Roots of a function of one parameter

We use the same cubic polynomial for our rootfinding test as for the 1D minimizer (Algorithm 17). R has a built-in 1D rootfinder, `uniroot`. This uses ideas in Brent (1973). As of UseR!2011 in Warwick, the R multiple-precision package `Rmpfr` (Maechler (2020)) did not have a rootfinder because it needed to have a pure-R code to extend the precision. During a quite period of the conference, the author (JN) translated the C code of `uniroot` to plain R, and it is now the `unirootR` function of `Rmpfr`. The code is in the `rootoned` package at http://download.r-forge.r-project.org/src/contrib/rootoned_2018-8.28.tar.gz.

Note that this is a different algorithm to that in Nashlib. Moreover, even the Nashlib codes are not necessarily fully equivalent, as over time minor variations have crept in. We are also fairly certain that the ideas of Algorithm 18 are NOT the best for performance. They were written initially for the Data General NOVA which had very poor quality floating point (24 bit mantissa, likely no guard digit, no double precision), and with very limited storage. Thus the programming goal was reliability rather than efficiency.

```
cubfn <- function(x) { x*(x*x-2)-5}
## curve(cubfn, from=-2, to=2)
cat("The first attempt fails -- see the plot of the function above.\n")
```

```
## The first attempt fails -- see the plot of the function above.
```

```
res <- try(uniroot(f=cubfn, lower=0, upper=1))
```

```
## Error in uniroot(f = cubfn, lower = 0, upper = 1) :
##   f() values at end points not of opposite sign
```

```
res <- try(uniroot(f=cubfn, lower=-3, upper=3))
cat("Root proposed is f(",res$root,")=",res$f.root,"\n")
```

```
## Root proposed is f( 2.094555 )= 3.690185e-05
```

```
cat("Tighter tolerance?\n")
```

```
## Tighter tolerance?
```

```
res <- try(uniroot(f=cubfn, lower=-3, upper=3, tol=1e-10))
cat("Root proposed is f(",res$root,")=",res$f.root,"\n")
```

```
## Root proposed is f( 2.094551 )= -7.01661e-14
```

```

BASIC

The code used here was edited from one dated August 30, 1976. Changes were needed to adapt to the changed syntax of the PRINT statement and to allow us to run the program inside a scripted environment, but the logic is unchanged. For example, we have artificially inserted a working set of values to start the Bisection / False Position rootfinder after the grid search. The original program was designed to present the grid search so that the user could interactively choose an interval for which the endpoints had different function values to start the rootfinder.

Pascal

Listing

Note that in this routine, we use bisection every 5 function evaluations. That is, we fix the `nbis` variable at 5. This could easily be changed to make it an input quantity.

?? Do we want to discuss why this may be useful?

```

procedure root1d(var lbound, ubound: real;
                 var ifn: integer;
                 tol : real;
                 var noroot: boolean );

var
  nbis: integer;
  b, fb, flow, fup : real;
  notcomp: boolean;

begin
  writeln('alg18.pas -- root of a function of one variable');

  notcomp := false;
  ifn := 2;
  nbis := 5;

```

```

fup := fnld(ubound,notcomp);
if notcomp then halt;
flow := fnld(lbound,notcomp);
if notcomp then halt;
writeln('f(',lbound:8:5,')=' ,flow,' f(',ubound:8:5,')=' ,fup);
if fup*flow>0 then noroot := true else noroot := false;
while (not noroot) and ((ubound-lbound)>tol) do
begin

    if (nbis * ((ifn - 2) div nbis) = (ifn - 2)) then
    begin
        write('Bisect ');
        b := lbound + 0.5*(ubound - lbound)
    end
    else
    begin
        write('False P ');
        b := (lbound*fup-ubound*flow)/(fup-flow);
    end;

    if b<=lbound then
    begin
        b := lbound;
        ubound := lbound;
    end;
    if b>=ubound then
    begin
        b := ubound; lbound := ubound;
    end;
    ifn := ifn+1;
    fb := fnld(b, notcomp);
    if notcomp then halt;
    write(ifn,' evalns: f(',b:16,')=' ,fb:10);
    write(confile,ifn,' evalns: f(',b:16,')=' ,fb:10);
    writeln(' width interval= ',(ubound-lbound):10);
    writeln(confile,' width interval= ',(ubound-lbound):10);
    if (ubound-lbound)>tol then
    begin
        if fb*flow<0.0 then
        begin
            fup := fb; ubound := b;
        end
        else
        begin
            flow := fb; lbound := b;
        end;
    end;
end;
writeln('Converged to f(',b,')=' ,fb);
writeln(' Final interval width =',ubound-lbound);
end;

```

Example output

First we compile the codes.

```
fpc ../Pascal2021/dr1618.pas
# copy to run file
mv ../Pascal2021/dr1618 ../Pascal2021/dr1618p.run
```

```
## Free Pascal Compiler version 3.0.4+dfsg-23 [2019/11/25] for x86_64
## Copyright (c) 1993-2017 by Florian Klaempfl and others
## Target OS: Linux for x86-64
## Compiling ../Pascal2021/dr1618.pas
## Linking ../Pascal2021/dr1618
## /usr/bin/ld.bfd: warning: link.res contains output sections; did you forget -T?
## 205 lines compiled, 0.1 sec
```

Then we run the grid search (Algorithm 16) followed by the Bisection / False position routine (Algorithm 18).

```
../Pascal2021/dr1618p.run <../Pascal2021/dr1618a.in >../Pascal2021/dr1618a.out

```

But we can run just the minimizer. Note that above we use only 13 function evaluations in the minimizer, but now use 17 (for the input used in this example). However, the grid search used 11 function evaluations prior to the call to the minimizer for a total of 24.

Example output

We solve the linear equations problem

$$Ax = b$$

for A being the Frank matrix and b the vector that is all 1s, that is, A times a vector of ones. Different orders of problem are tried. This problem has an obvious solution, which is that

$$x_i = 1$$

and the elements of A are integers, so we can compute the error in the solution as well as the residual

$$b - Ax$$

```

A <- matrix(0, nrow=5, ncol=5)
b <- rep(1,5)

for (i in 1:5) {
  for (j in 1:5){
    A[i,j]=min(i,j)
  }
}
print(A)

```

```

##      [,1] [,2] [,3] [,4] [,5]
## [1,]    1    1    1    1    1
## [2,]    1    2    2    2    2

```

```
## [3,] 1 2 3 3 3
## [4,] 1 2 3 4 4
## [5,] 1 2 3 4 5
```

```
C <- A %*% b
print(C)
```

```
##      [,1]
## [1,] 5
## [2,] 9
## [3,] 12
## [4,] 14
## [5,] 15
```

Note that the program, as given, is single precision, so some of the results are not terribly accurate. Also the control IMULT is an upper limit on the number of matrix multiplications before the process is artificially halted. We still get an approximate solution at this stage, and the result accuracy in terms of residuals and error.

```

Example output

We use the same example as for Algorithm 15, with A the unit matrix and B the Frank matrix, here of order 5.

Note that we could modify the program to work with $-A$ to get the negative of the largest eigenvalue. Various shifting strategies might be used to get other solutions, but they are rather inconvenient and not recommended.

function calceps:real;
{calceps.pas ==
    This function returns the machine EPSILON or floating point tolerance,
    the smallest positive real number such that 1.0 + EPSILON > 1.0.
    EPSILON is needed to set various tolerances for different algorithms.
    While it could be entered as a constant, I prefer to calculate it, since
    users tend to move software between machines without paying attention to
    the computing environment. Note that more complete routines exist.

{matrixin.pas --

    This procedure generates an m by n real matrix in both
    A or avector.

```

```

A is of type rmatrix, an array[1..nmax, 1..nmax] of real
where nmax >= n for all possible n to be provided.

avector is of type rvector, an array[1..nmax*(nmax+1)/2]
of real, with nmax as above.

sym is set true if the resulting matrix is symmetric.

function calceps:real;
{calceps.pas ==
    This function returns the machine EPSILON or floating point tolerance,
    the smallest positive real number such that 1.0 + EPSILON > 1.0.
    EPSILON is needed to set various tolerances for different algorithms.
    While it could be entered as a constant, I prefer to calculate it, since
    users tend to move software between machines without paying attention to
    the computing environment. Note that more complete routines exist.
